## 1. Introduction

Low resolution atmospheric models generally have less tropical variability on time scales of several days than is observed (e.g. [1]). Stochastic physics (SP) may reduce this bias by increasing the variability in the simulated tropical convection. SP has already been shown to improve NWP skill and reduce some biases in the mean state [2,3]. Here we quantify the impact of SP on tropical variability in the ECMWF seasonal forecasting system (System 4). We also quantify the impact on simulating tropical precipitation extremes, which have large societal impacts [2].

## 2. Data

- We use seasonal hindcasts of daily-mean precipitation from System 4 and compare these with equivalent hindcasts with the SP schemes deactivated (DET).
- These begin on May 1 and Nov 1 of each year between 1998–2010 and we use hindcast months 2–7.
- 10 ensemble members are used so that sampling variability is small.
- System 4 uses two SP schemes: the Stochastically Perturbed Parametrization Tendencies Scheme (SPPT) and the Spectral Stochastic Backscatter Scheme (SPBS) [2]. Comparing with hindcasts with just one of SPPT or SPBS activated indicates that most of the effects of SP are due to SPPT (not shown).

We also compare the model output with the observational GPCP 1DD and TRMM 3B42 V7 datasets. Note that these show considerable differences in the estimated precipitation amounts in individual heavy rainfall events, suggesting there is considerable uncertainty in the true variability, so comparisons with the model data should be made cautiously.

## 3. Impact on the standard deviation of precipitation

## Why do we see a systematic impact on the model climate with SPPT?

- Product of two random variables?
  - Product distribution depends crucially on input distributions (tendencies)
  - Product of two normally distributed variables with  $\mu=0$  is “well behaved” distributed (e.g. symmetric)
  - This is not generally the case, especially not for  $\mu \neq 0$
- Nonlinear thresholds (e.g. trigger for convection)?
- Asymmetric nature of  $q$  and precipitation?
- Tuning of the model for deterministic formulation versus stochastic model?
- Tapering of the boundary layer and related inconsistencies?

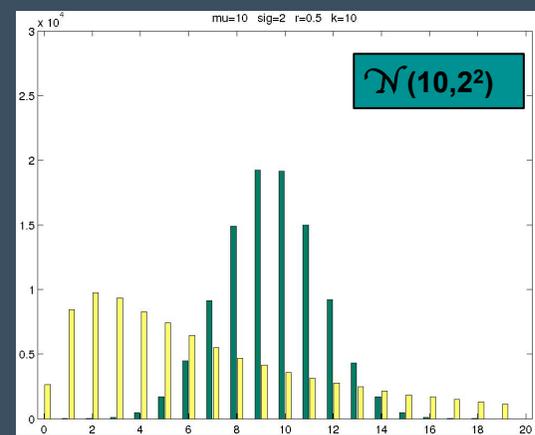

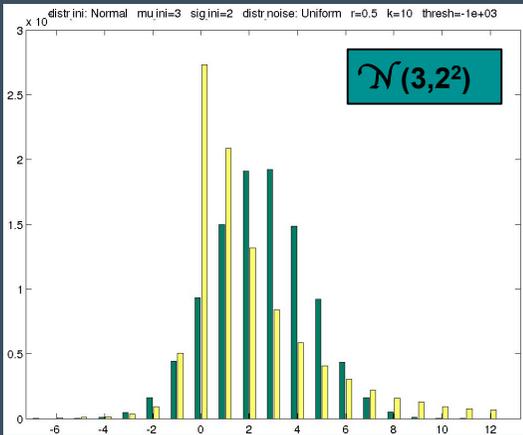

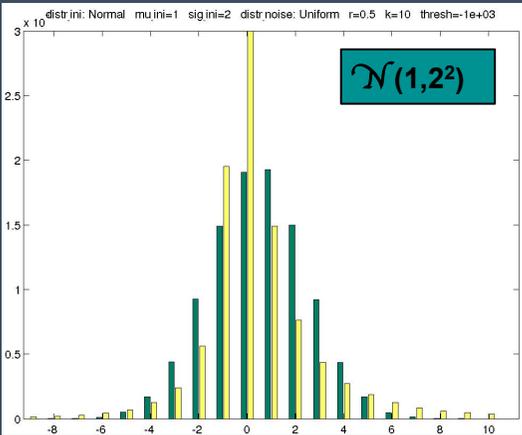

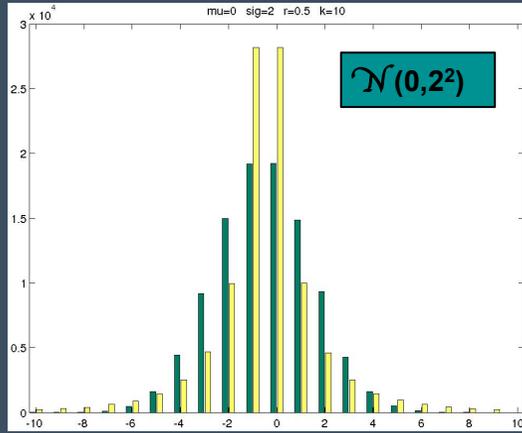

# Multiplicative noise

$X \sim \mathcal{N}(\mu, \sigma^2)$  ... initial distribution of  $X$

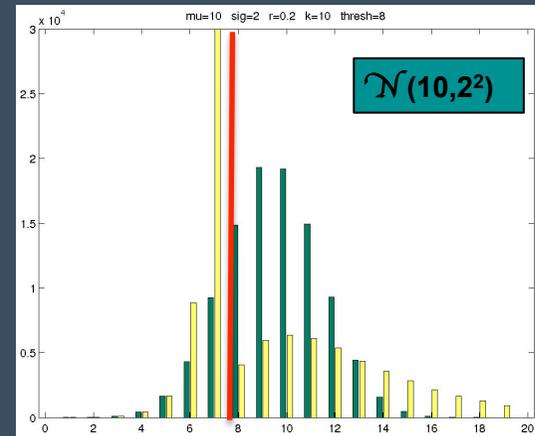

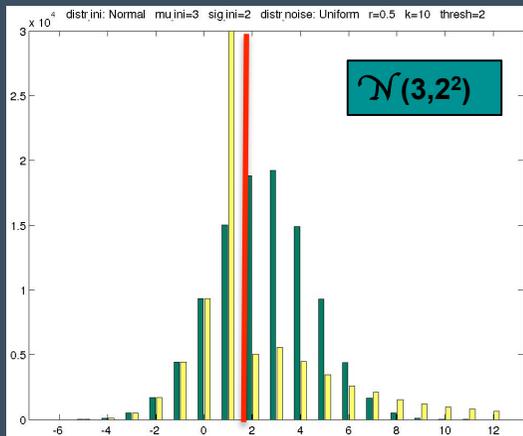

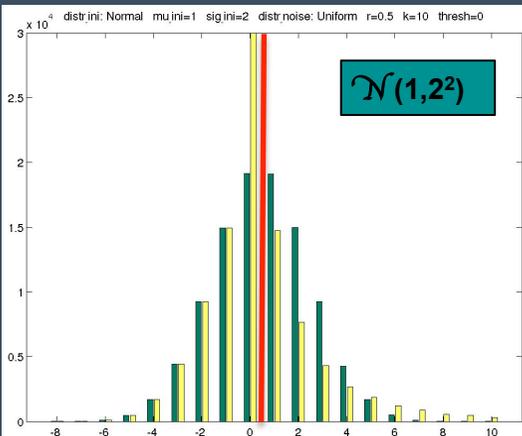

$r \sim \mathcal{U}(0.5, 1.5)$  ... distribution of random noise  $r$

product distribution

### INTRODUCTION

Methods to explicitly represent uncertainties in weather and climate models have reduced model biases and improved forecast skill when implemented for the atmosphere. However, these methods have not yet been applied to the land surface.

At certain times and in certain places the land surface is strongly coupled to the atmosphere, such as during the 2003 heatwave over Europe when dry soil led to extreme summertime temperatures. Improvements in the representation of uncertainty in the land surface may then lead to improvements in forecast for the atmosphere in cases like this.

We analyze seasonal experiments performed with the ECMWF weather and seasonal climate forecasting model, the Integrated Forecasting System (IFS), with different kinds of perturbation made to the land surface, in order to investigate the effect of explicitly incorporating uncertainty in this domain.

### EXPERIMENTS

The control experiment setup is as follows:

- Four month forecast initialised at the start of every May for 1981-2013
- 25 member ensemble, with initial condition perturbations.
- Atmosphere: IFS Cycle 41R1, T255 resolution, 91 vertical levels. Atmospheric stochastic schemes SPPT & SKEB switched on.
- Ocean: NEMO 1 degree, 42 vertical levels

### CONCLUSIONS

Previous work with CY36R4 showed that by perturbing land surface parameters with a constant perturbation, forecasts of the hot 2003 European summer are improved (MacLeod et al 2015). Building on this work, we show here that perturbing parameters in CY41R1 gives large improvements in terms of soil moisture reliability, particularly for less frequent events (quintiles).

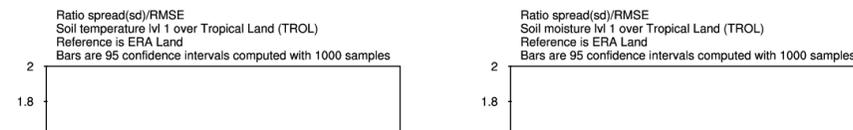

Experiments with stochastic parameters and tendencies have also been carried out, but these do not show the improvement in reliability seen for the static perturbed parameter experiment. Of these, the experiment which uses the "slowest" scale most closely replicates the PP result, however the improvement is not as great.

The model spread/error ratio is increased with perturbation. For soil moisture the SP experiments give the largest improvement, however the PP experiment gives an unusually large increase in spread of soil temperature despite only perturbing soil hydrology parameters.

Future work at ECMWF is now looking at perturbations to the land-atmosphere coupling parameter.

### RESULTS

#### Impact on spread

## Summary

1. Atmospheric stochastic physics and model bias in the coupled ECMWF model
  - Reduction of tropical biases in convective areas
2. Impact of atmospheric stochastic physics on climate forecast quality
  - Improvements in the tropics
3. Non-conservation of humidity with SPPT
  - (Temporary) fix to SPPT to ensure conservation of humidity (and temperature) tendencies
4. Model uncertainty of the land surface
  - Impact varies across regions and perhaps most noticeable for extreme events

## CLIMATE SPHINX

*Climate **SPHINX** (Stochastic Physics High Resolution Experiments) is a PRACE EU project which aims to investigate the sensitivity of climate simulations to model resolution and stochastic parameterizations, and to determine if very high resolution is truly necessary to facilitate the simulation of the main features of climate variability.*

SPHINX is a project by **ISAC-CNR**, lead by Jost von Hardenberg, in collaboration with Oxford University (Tim Palmer and Antje Weisheimer group).
